ABSTRACT

Objective: Relatively rare case.
Background: Myositis ossificans is a benign condition which appears as a heterotopic, well-defined bone formation in muscles and soft tissues. It is most common in children and young athletes. Most myositis ossificans occur in the large muscles of proximal extremities such as the quadriceps and brachialis and it is rare to occur in the lumbar spine.
Case Report: We present a case of a 12 year-old Japanese boy with severe lower back pain. On physical examination, a severe tenderness and swelling was present in the left lumbar region, at level of L4/5. He had a traumatic history of his back. He hit nunchak (one of tools of Chinese martial arts) on the back when he was practicing it at school three months ago.
Both lumbar radiograph and lumbar Computed Tomography (CT) examination showed a ring like osteoblastic lesion calcification around left facet joint of L4/5 suggestive of myositis ossificans. He received conservative treatment. His back pain and swelling disappeared in 2 months. Follow up lumbar CT examination 8 months later showed the osteoblastic lesion calcification was more prominent than the one in the previous CT. Soft tissue swelling around the osteoblastic calcific area was not detected.
Conclusion: This case was unusual location for myositis ossificans. Careful correlation of the clinical and radiological findings is necessary to avoid surgical treatment.

KEYWORDS: Myositis ossificans; Computed Tomography (CT); Lumbar spine.

INTRODUCTION

Myositis ossificans is a benign condition which appears as a heterotopic, well-defined bone formation in muscles and soft tissues, typically involving muscles, tendons, ligaments, fascia, and aponeurosis. It is usually found in children and young athletes. Although the exact etiology remains unclear, it is most commonly reported after major traumatic events, and to larger muscle groups. We present a rare case of myositis ossificans in the lumbar spine.

CASE REPORT

A 12 year-old Japanese boy with severe low back pain was hospitalized to our hospital. He was 157 cm tall and 45 kg weight and had no history of sports activities. This low back pain had been restricting his motion more than one month. He had a history of trauma three months ago: he used one of Chinese martial arts at school and practiced nunchak (one of tools of Chinese martial arts). He hit the nunchak on his back. After that, his lower back gradually swollen up and the lower back pain developed afterwards in 2 months. On physical examination, a severe tenderness and swelling was present in the left lumbar region, at level of L4/5. There was no erythema. The laboratory findings were normal. Neurological examina-
tion revealed no motor or sensory deficits, with normal reflexes. Both lumbar radiographs and lumbar Computed Tomography (CT) showed a ring like calcification adjacent to left facet joint of L4/5 (Figures 1 and 2). There was no evidence of bone fracture in the lumbar spine. Lumbar Magnetic Resonance Imaging (MRI) showed high signal intensity area along the left multifidus muscle on T2-weighted axial image (Figure 3A). Short TI Inversion Recovery (STIR) sagittal image showed bone marrow edema at left lamina of L4/5 was demonstrated (Figure 3B). Faint low signal component suggestive of calcification was visualized around the left facet joint of L4/5 (Figures 4A and 4B). There was no nerve root signal abnormality. Both clinical and radiological findings were compatible with myositis ossificans. He received conservative treatment. His back pain and swelling disappeared in 2 months. Follow up lumbar CT 8 months later showed calcification became dense as compared to the one in the previous CT (Figure 4). Soft tissue swelling along the left multifidus muscle was improved.

**DISCUSSION**

Most myositis ossificans occur in the large muscles of proximal extremities such as the quadriceps and brachialis. It is rare to occur in the lumbar spine. As long as I surveyed, only 3 cases of myositis ossificans in lumbar spine were found on PubMed line. Interestingly, all of the 3 cases had no traumatic history like our case. It could be because the muscle contusion by playing sports might be rarer in the spine than in the extremities. In a small number of cases, possible etiologies include infections, burns, neuro-muscular disorders, hemophilia (factor-IX
deficiency), tetanus, and drug abuse. We should also consider myositis ossificans if we find these etiologies.

Jocobsen S reported from his animal experiments that connective tissue injury of muscle gives stimulation to both fibroblasts and osteoblasts and these cells deposit and structure osteoid centripetally in the lesion. As the lesion matures, cancellous bone develops into mature, lamellar bone in the periphery of the lesion. In addition, repetitive minor mechanical injuries, ischemia or inflammation have been implicated as possible causative factors.

In our case, calcification became denser in the follow-up CT, which is suggestive of mature bone. This change is typical for myositis ossificans.

Myositis ossificans is a benign, self-limiting disease. Treatment in most cases is conservative; rest, ice, and anti-inflammatory drugs to relieve pain. Typically, a regression of the symptoms is seen in the course of disease (30%). Surgical intervention is recommended when the heterotopic bone has matured like our case. The optimum time for a surgery excision is between 9 and 12 month after the trauma.
CONCLUSION

This case is the rare localization for a myositis ossificans. It was typical findings on CT examination that heterotopic bone had matured.
