ABSTRACT

Background: Brainstem gliomas (BSG) are Central Nervous System (CNS) tumors with a median survival time of approximately 9 months. Up to now chemotherapy has not shown to improve survival in these patients. The outcome of Radiation Therapy (RT) in combination with Nimotuzumab is shown in the present report.

Material and Methods: 28 children and adolescents were included between Jan/2009 and Dec/2012 with the diagnosis of BSG and follow-up till January 2015. All patients had Diffuse infiltrative Pontine Gliomas (DIPG) and were irradiated with a dose ranging from 54 to 59.6 Gy at the National Oncology and Radiobiology Institute in Havana, Cuba. Three patients were planned with IMRT and 25 with 3D Conformal RT. Nimotuzumab was indicated at the dose of 150 mg/m2 weekly during the time of RT treatment, then every 15 days during 8 weeks and finally monthly for 1 year. Univariate and multivariate Cox regression models and Kaplan Meier survival were analyzed to evaluate the survival.

Results: Median age at diagnosis was 7 years (range 3-18 years old), median overall survival was 17.3 months (95% CI 14.0-20.5 ) since the beginning of the treatment and the accumulated survival at 5 years of treatment was 42.9%. There was balance in sex, age and dosage of RT in the population. Addition of Nimotuzumab to RT was safe.

Conclusions: The combination of Radiotherapy and Nimotuzumab were well tolerated in this brainstem tumours patient’s series.

KEYWORDS: Radiotherapy; Nimotuzumab; Brainstem tumors children adolescents.

INTRODUCTION

The brainstem is defined as the midbrain, pons and medulla; brainstem gliomas are generally diffuse intrinsic tumors involving the pons, with defined clinical presentation and characteristic appearance in imaging findings and do not require pathological confirmation;1-4 it can extend along neural tracts to adjacent regions of the brain, so it has been defined as fatal disease. Radiation treatment response rates show low degrees of efficacy, with short-term responses and a median overall survival less than one year;5-8 Diffusely infiltrating pontine glioma...
mas must be distinguished from other subsets of diffuse intrinsic pontine gliomas, such as focal tumors, which are described with better prognosis and longer term survival.\textsuperscript{5,9}

The association of Chemotherapy (ChT) and radiotherapy (RT) have not improved survival\textsuperscript{1,6-8,10,11} and now biologics are combined with RT in clinical trials.\textsuperscript{9,12,13}

We investigated the association of RT with Nimotuzumab, a humanized monoclonal antibody developed at the Center of Molecular Immunology, Havana, Cuba and testing the hypothesis that this combination will improve survival in these tumors. The antibody was obtained by humanization of the murine antibody EGF/R3.\textsuperscript{14} Because Nimotuzumab has a 10 fold lower affinity to the EGFR, as compared to cetuximab, its capacity to bind EGFR is heavily dictated by cell receptor density.\textsuperscript{15} Nimotuzumab preclinical and clinical characterizations have been summarized before.\textsuperscript{16-18}

A distinguishing feature of Nimotuzumab compared to other mAbs of the EGFR class is the lack of severe skin toxicity and the possibility to be used beyond progression.\textsuperscript{16,19}

MATERIAL AND METHODS

We conducted a prospective, non-randomized clinical study, with a treatment group of 28 children and adolescents (range 3 to 18 years) with the diagnosis of diffuse intrinsic pontine glioma (DIPG) documented by imaging (MRI, CT scan). Biopsy and histology confirmation were not a requirement of this study. This study covers a sequential period between Jan/2009 and Dec/2012. Follow-up continued to September 2014. Patients with focal lesion of the brainstem were not eligible for the study, because these are described with a better prognosis.\textsuperscript{5,9} Also excluded were those who had received prior chemotherapy or radiotherapy.

The study was approved by the Ethical Institution Committee at the National Oncology and Radiobiology Institute (INOR), Havana and informed consent obtained from the patients’ parents. All patients were irradiated at INOR, and received the monoclonal antibody Nimotuzumab at INOR or at the Pediatric Hospital “Juan Manuel Marques”, also in Havana. Male patients: 14, and female: 14.

No surgical treatment was feasible, and in 3 there were pathologic results by biopsy. In all patients tumor was extended to the pons.

Linear Accelerator was used for a radiation treatment: Gross Tumour Volume (GTV) was defined as the visible tumor, either by MRI or CT; Clinical Target Volume (CTV) accounted for subclinical microscopic disease and unappreciated tumor extension, generally 1.5 cm from the GTV, and Planning Target Volume (PTV) was 0.3-0.5 cm and could vary according to the Organ at Risk.\textsuperscript{4,20} RT doses range from 54 to 59.8 Gy, with dose per fraction 1.8 Gy. Three patients were planned with IMRT and the rest with 3D CT. In all patients a thermoplastic mask was fitted.

Nimotuzumab was administered at a dose of 150 mg/m\textsuperscript{2} (IV), weekly during the term of RT, then every 2 weeks for 8 doses, then monthly for one year. In the last patients included it was prolonged for 2 years.

Twenty four patients (85.7\%) received the complete Nimotuzumab schema, in 4 there were minor interruptions of the dosage because patients did not concur with the treatment option in a timely manner. Characters of the series are in Table 1.

| Median age at diagnosis……………….. 7 years old ( range 3-18 years ) |
| Male/female ratio………………………… 1:1 |
| Type of tumor……………………………..DIPG:28 |
| Localization……………………………………Mid brain and pons: 15 |
| Pons:6 |
| Cerebello-pontine: 4 |
| Not specified: 3 |
| Pathology…………………………………………Grade II Astrocytoma:2 |
| Grade III Astrocytoma: 1 |
| Not biopsied: 25 |
| Radiotherapy dose received……………………………54-57 Gy : 4 patients |
| 57-59 Gy: 15 patients |
| 59, 8 Gy: 9 patients |
| Nimotuzumab treatment…………………………….Completed: 24 |
| Not completed: 4 |

Table 1: Charts of the series of brainstem gliomas in children and adolescents.

Univariate and multivariate Cox regression models were fitted in order to identify possible predictors of survival and Kaplan Meier survival was calculated for all cases.

RESULTS

Median age of the cases at diagnosis was 7 years (range between 3 and 18 years old). Twenty eight cases were DIGP, but in all cases tumor extended to pons, and in one case also to 4th ventricle, cerebellum and hypothalamus.

The diagnosis was made by clinical and imaging findings except in 3 cases where pathological examination was also done, one with astrocytoma grade II and the 2 others with astrocytoma grade III, all alive. Median overall survival from the beginning of treatment was 17.5 months, 95% CI (14.1-20.7) and Kaplan Meier survival accumulated was 42.9\% at 2 years, established till 5 years of RT treatment. At present, (January
2015) 12 of the patients are alive (2 less than 2 years, 3 between 2-3 years, 5 between 4-5 years and 2 with more than 5 years of follow-up). Therapeutic results were compared with a previous case series of 22 children and adolescents with BSG treated with the same mode of irradiation, but without Nimotuzumab during 1992-2008 at the same institution (Instituto Nacional de Oncología y Radiobiología in Havana.) (Figure 1)

Sex

14 female patients had a 44.0% survival at 2 years and counting, and 14 male patients a 33.3 % survival. (Figure 2)

Five patients received a dose between 54-57 Gy, with a survival rate of 60% at 2 years and counting; 16 patients with a dose between 57-59 Gy with a survival rate of 41.2% at 2 years plus, and 7 patients received 59.8 Gy with a survival rate of 22.2% at 2 years plus. Radiation dose was increased in those patients where DIPG tumor size exceeded the mean. (Figure 3)

By Age Group

6 patients in the group up to 4 years old (21.5%) with a survival rate of 25% at 2 years plus; 15 patients between 5-9 years old (53.6%) with a survival rate of 37.5% at 2 years plus; 4 patients between 10-14 years old (14.4%) with a survival rate of 67%; and 3 patients with 15-18 years old age (10.7%) with a survival rate of 50% at 2 years plus (Figure 4).
Multivariate analysis showed no significant differences according to sex, age and dose of irradiation received, nor with the dosage of Nimotuzumab, with a tendency for best survival in age group 10-18 years old and with the dose at 54-57 Gy.

Treatment was well tolerated and no grade III or higher grade toxicity was observed. The most frequent adverse event was alopecia in irradiation fields, observed in 27 patients (96.4%). Other reported adverse events were vomiting, headache, fever, tremor and nausea, in less than 40% of patients (Table 2).

At the end of irradiation there was a clinical response in 27 patients (96.4 %), only one patient had no response to RT treatment.

DISCUSSION

Brainstem gliomas are a heterogeneous group of tumors that occur predominately in children, have a characteristic appearance in MRI and CT and do not require pathological confirmation: clinical and imaging are considered sufficient for diagnosis; they have a bad prognosis despite initial response to irradiation, which has been the ideal treatment, with a median survival of one year or less. Radiation dose escalation increases toxicity but does not improve outcome; neither chemotherapy nor hypofractionation have improved therapeutic ratio.

Brainstem gliomas could be diffuse intrinsic pontine gliomas (DIPG) and comprise an entity defined by imaging involving pons. Pontine localization was found to be a negative prognostic factor; they have a bad prognosis despite initial response to irradiation, which has been the ideal treatment, with a median survival of one year or less. Radiation dose escalation increases toxicity but does not improve outcome; neither chemotherapy nor hypofractionation have improved therapeutic ratio.

Our series of 28 children and adolescents with prolonged treatments involving Nimotuzumab in conjunction with RT showed a median overall survival of 17.3 months and a survival rate at 2 years of 39.7%, exceeding those of earlier reports, and of more recent ones. In a previous case series of patients treated only with RT during the period 1992-2008 in the same Institution (National Oncology and Radiobiology Institute, in Havana), median survival time was 10.0 months and the survival rate at 2 years was 15%. We know that the use of retrospective case series as control groups have limitations, but there are facts that are relevant: all cases were irradiated in the same Institution, so there could not exist center-effects that could bias patient groups.

It is remarkable that in our series there is a preliminary benefit to survival in older ages; it contrasts with reports that young age may predict a better outcome for children with diffuse pontinegliomas. Best results were obtained in the group that received 54-57 Gy of RT dosage; increasing RT dosage did not yield better results, consistent with.

The prolonged use of Nimotuzumab for one year or more was well tolerated: adverse events such as alopecia and dermatitis were related to irradiation. Cutaneous rash was also reported but not related; other minor adverse events could be related in part with the clinical evolution of the tumor and the radiation treatment. Nimotuzumab is a humanized monoclonal antibody that recognizes the EGF external domain with intermediate affinity (kd=10-8) that has shown a benefit in addition to RT in different studies. In children it has been reported with good results and safely associates to RT in CNS and Head and Neck tumors.

CONCLUSION

The association of focal RT and Nimotuzumab in the treatment of brainstem tumors in children and adolescents was a therapeutic option in order to increase overall survival and support the possibility of new trials with this combination. Radiation dose over 57 Gy did not increase possibilities of survival in our series.
